### DESCRIPTION

G proteins, also known as guanine nucleotide-binding proteins, are a group of proteins that operate as molecular switches inside cells, conveying signals from a range of external stimuli to the cells interior. Their ability to bind to and hydrolyze Guanosine Triphosphate (GTP) to Guanosine Diphosphate (GDP) is regulated by variables that control their activity (GDP). They are 'on' while GTP is bound, and 'off' when GDP is bound. G proteins are a subset of GTPases, a wider class of enzymes.

G proteins are divided into two groups. The first are monomeric small GTPases (small G-proteins), while the second are heterotrimeric G protein complexes. The alpha, beta, and gamma subunits make up the latter type of complexes. In addition, the beta and gamma subunits can form the beta-gamma complex, which is a stable dimeric complex.

G Protein-Coupled Receptors (GPCRs) that bridge the cell membrane activate heterotrimeric G proteins within the cell. Signaling molecules bind to an external GPCR domain, which activates a specific G protein, which is then activated by an internal GPCR domain. G proteins have been found to be "pre-coupled" with several active-state GPCRs. The G protein triggers a series of further signaling events, culminating in a change in cell function. G Protein-Coupled Receptors (GPCRs) that bridge the cell membrane activate heterotrimeric G proteins within the cell. Signaling molecules bind to an external GPCR domain, which activates a specific G protein, which is then activated by an internal GPCR domain. G proteins have been found to be "pre-coupled" with several active-state GPCRs. The G protein

triggers a series of further signaling events, culminating in a change in cell function. In cells, G proteins play a crucial role in signal transduction "many disorders, including diabetes, blindness, allergies, depression, cardiovascular abnormalities, and certain types of cancer, are caused by malfunction of GPCR (G Protein-Coupled Receptor) signaling pathways. Around 30% of current medications' biological targets are thought to be cancer cells "GPCRs are a type of gene-related peptide receptor G protein-coupled receptors detect photons of light, hormones, growth factors, medicines, and other endogenous ligands, and the human genome encodes about 800 of them. Around 150 GPCRs in the human genome have yet to be discovered. RGS proteins inactivate G proteins that have been activated by G protein-coupled receptors (for "Regulator of G protein signaling"). GTP binding is aided by receptors (turning the G protein on). Hydrolysis of GTP is aided by RGS proteins.

G proteins are used for signaling in all eukaryotes, and there is a great diversity of G proteins. Humans, for example, encode 18 G proteins, 5 G proteins, and 12 G proteins.

G protein can refer to two different protein families. Heterotrimeric G proteins, sometimes known as "big" G proteins, are made up of alpha ( $\alpha$ ), beta ( $\beta$ ), and gamma ( $\gamma$ ) subunits and are activated by G protein-coupled receptors. The Ras superfamily of small GTPases includes "small" G proteins (20 kDa-25 kDa). These proteins are similar to the alpha ( $\alpha$ ) component found in heterodimers; however they are monomeric and only contain one unit. They do, however, bind GTP and GDP and are involved in signal transduction, just like their bigger counterparts.
